# A BEAM-BEAM TUNE SHIFT SEMI-EMPIRICAL FIT 

M. Bassetti, M.E. Biagini<br>INFN-LNF, C.P. 13, 00044 Frascati (RM),Italy

#### Abstract

A new approach to the beam-beam limit, taking into account the effect of the energy fluctuations and of the electric field work on colliding particles, is presented. A formula is derived by a fit of data collected at several colliders with energies ranging in two orders of magnitude.

## 1. Introduction

The comprehension of the so-called "beam-beam limit" is one of the major problems in the theory of electron storage rings. By squeezing the beams we can theoretically get an infinite luminosity, but this actually never happens. For given values of the machine parameters we find instead a limit. Once working energy, beam current and machine optics are fixed, to optimise the luminosity there is only one degree of freedom left, that we can choose among many related parameters as the vertical tune shift $\xi_{\mathrm{y}}$, the ratio "r" between the rms beam sizes $\sigma_{y}$ and $\sigma_{x}$, the coupling parameter " $\kappa$ ", etc. A first study to the beam-beam limit, the so-called "Amman-Ritson" optical interpretation", states that the limit should be the same on $\xi_{\mathrm{x}}$ and $\xi_{\mathrm{y}}$ and independent on the energy, if the working point is chosen far away from resonance lines. The first experimental results on the ADONE storage ring, in Frascati, showed ${ }^{2}$ ) instead a violent dependence on the energy below 1 GeV . Spear, VEPP-2M and other colliders confirmed this behaviour ${ }^{3}$. At the lowest energies colliders show a luminosity scaling $L \approx E^{6 \div 7}$ instead of the expected behaviour $\mathrm{L} \approx \mathrm{E}^{4}$. This seems to happen up to an energy characteristic of each collider, that we call threshold energy (TE). Above TE the tune shift limit slightly depends on the beam energy.

A new attempt for the comprehension of the beam-beam limit is presented in this paper. We limit ourselves to flat beams colliders, working above TE. We suppose that two phenomena are candidates to play an important role in the beam beam interaction:

- the energy fluctuation of the single particle which characterises the synchrotron radiation;
- the work done by the electric field component of a beam on each particle of the opposite beam.

## 2. Beam-beam tune shift from luminosity measurements

Usually published data in literature concern luminosity, emittance and beam current measurements only. To know other important machine parameters, needed for our analysis (as $\sigma_{\mathrm{x}}, \sigma_{\mathrm{y}}, \kappa, \xi_{\mathrm{x}}$ and $\xi_{\mathrm{y}}$ ) we use the luminosity formula:

$$
\begin{equation*}
\mathrm{L}=\frac{\mathrm{f}_{\mathrm{o}} \mathrm{n}_{\mathrm{b}} \mathrm{~N}^{2}}{4 \pi \sigma_{\mathrm{x}} \sigma_{\mathrm{y}}} \tag{1}
\end{equation*}
$$

Knowing L, the number of bunches $\mathrm{n}_{\mathrm{b}}$ and the number N of particles per bunch, we can compute the beam cross section $\sigma_{\mathrm{x}} \sigma_{\mathrm{y}}$, even if the transverse beam sizes are not known separately. In the most general case of non zero dispersion at the I.P., it is:

$$
\begin{equation*}
\sigma_{\mathrm{x}}=\sqrt{\left[\varepsilon_{\mathrm{s}}+\varepsilon(1-\mathrm{q}) \beta_{\mathrm{x}}\right]} \quad \sigma_{\mathrm{y}}=\sqrt{\varepsilon \beta_{\mathrm{y}} \mathrm{q}} \tag{2}
\end{equation*}
$$

where $\varepsilon$ is the off coupling betatron emittance, $\varepsilon_{\mathrm{s}}$ the synchrotron contribution to the emittance of the dispersion at the I.P. and $q=\kappa /(1+\kappa)$. With a little bit of algebra we can deduce the coupling factor $\kappa$ and the beam sizes from $L$. Then the tune shifts can be computed by the well known formula:

$$
\begin{equation*}
\xi_{\mathrm{x}, \mathrm{y}}=\frac{\mathrm{r}_{\mathrm{e}} \mathrm{~N} \beta_{\mathrm{x}, \mathrm{y}}}{2 \pi \gamma \sigma_{\mathrm{x}, \mathrm{y}} \sigma_{\mathrm{x}}\left(1+\sigma_{\mathrm{y}} / \sigma_{\mathrm{x}}\right)} \tag{3}
\end{equation*}
$$

For our fit we will use the tune shifts as computed from eq. (3), rather than the measured ones: in fact it is worthwhile to point out that often the experimental vertical tune shift is computed from the ratio $\mathrm{L} / \mathrm{I}$, neglecting the beam sizes contribution from $\sigma_{\mathrm{y}} / \sigma_{\mathrm{x}}$ in eq. (3).

## 3. A guiding hypothesis

Let us consider now some luminosity data available in literature ${ }^{4,5)}$, some of them being unfortunately very old. We consider for our purposes the aformentioned variables:

1) the average energy fluctuations $\Delta \mathrm{E}_{\mathrm{F}}$ of each particle between two successive interactions. From Ref. 6) we have:

$$
\begin{equation*}
\Delta \mathrm{E}_{\mathrm{F}}[\mathrm{KeV}]=16.11294 \frac{\mathrm{E}[\mathrm{GeV}]^{3.5}}{\rho_{\mathrm{F}}[\mathrm{~m}] \sqrt{\mathrm{N}_{\mathrm{i}}}} \tag{4}
\end{equation*}
$$

$\mathrm{Ni}_{\mathrm{i}}$ is the number of Interaction Points (I.P.) per turn and $\rho_{\mathrm{F}}$ is the equivalent machine bending radius in presence of dipoles and wigglers ${ }^{7}\left(\rho_{F}=\sqrt{ } 2 \pi / I_{3}\right)$;
2) the work $\mathrm{W}_{\mathrm{el}}$ done by the electric field of a beam on particles of the opposite beam. This work exists also when the beams collide head-on, because every particle trajectory has a slope at the I.P. which creates an electric field component parallel to the trajectory itself. $\mathrm{W}_{\mathrm{el}}$ acts on both planes. It is approximately:

$$
\begin{equation*}
\mathrm{W}_{\mathrm{el}} \approx \frac{1}{2} \mathrm{~m}_{\mathrm{o}} \mathrm{c}^{2} \gamma\left[\left\langle\Delta \mathrm{x}^{\prime 2}>\sigma_{\mathrm{x}}^{\prime}{ }^{2}+\left\langle\Delta \mathrm{y}^{\prime 2}>\sigma_{\mathrm{y}}^{\prime}{ }^{2}\right]^{1 / 2}\right.\right. \tag{5}
\end{equation*}
$$

In fact $\left\langle\Delta x^{\prime 2}\right\rangle^{1 / 2}$ and $\left\langle\Delta y^{\prime 2}\right\rangle^{1 / 2}$ are proportional to the transverse electric field of the beam-beam and $\sigma_{x}^{\prime}$ and $\sigma_{y}^{\prime}$ determine the fraction of the electric field component that acts on the particle.

Our guiding hypothesis is that $\mathrm{W}_{\mathrm{el}}$ can create a mechanism of instability and the noise $\Delta \mathrm{E}_{\mathrm{F}}$ can neutralise this mechanism. We may compare $\mathrm{W}_{\mathrm{el}}$ to a radio signal with very high correlation and $\Delta \mathrm{E}_{\mathrm{F}}$ to a noise. $\Delta \mathrm{E}_{\mathrm{F}}$ must be large enough to cancel out the signal $\mathrm{W}_{\mathrm{el}}$. We expect $\Delta \mathrm{E}_{\mathrm{F}}$ to be much larger than $\mathrm{W}_{\mathrm{e}}$, due to the very sharp Fourier spectrum of $\mathrm{W}_{\mathrm{el}}$ with respect to the very wide $\Delta \mathrm{E}_{\mathrm{F}}$ one.
For the $\left\langle\Delta x^{\prime 2}\right\rangle$ and $\left\langle\Delta y^{\prime 2}\right\rangle$ values we assume the results deduced in Ref. 8),9):

$$
\begin{equation*}
\left\langle\Delta \mathrm{x}^{\prime 2}\right\rangle=\left\langle\Delta \mathrm{y}^{\prime 2}\right\rangle=\frac{4 \mathrm{r}_{\mathrm{e}}^{2} \mathrm{~N}^{2}}{\gamma^{2} \sigma_{\mathrm{x}}^{2}} \eta_{\mathrm{o}}(\mathrm{r}) \tag{6}
\end{equation*}
$$

where $r=\sigma_{y} / \sigma_{x}$ and the function $\eta_{0}(r)^{8)}$ is:

$$
\begin{equation*}
\eta_{0}(\mathrm{r})=\frac{1}{\sqrt{D}} \arctan \left[\frac{\sqrt{D}}{\mathrm{Q}}\right] \tag{7}
\end{equation*}
$$

with D and Q defined by:

$$
\begin{gather*}
\mathrm{D}=3 \mathrm{r}^{4}-10 \mathrm{r}^{2}+3  \tag{8}\\
\mathrm{Q}=3 \mathrm{r}^{2}+8 \mathrm{r}+3 \tag{9}
\end{gather*}
$$

The function $\eta_{0}(r)$ has an analytical continuation for $\mathrm{D}<0: \sqrt{\mathrm{D}}$ becomes $\sqrt{\mathrm{abs(D)}}$ and the function arctan becomes arctanh. For each value of $r$ between 0 and 1 a good approximation is:

$$
\begin{equation*}
\eta_{0}(\mathrm{r})=\frac{0.302}{1+2.2 \mathrm{r}+\mathrm{r}^{2}} \tag{10}
\end{equation*}
$$

If there is a synchrotron emittance at the IP, $\eta_{0}(\mathrm{r})$ becomes:

$$
\begin{equation*}
\eta\left(\mathrm{r}, \frac{\beta_{\mathrm{x}}}{\beta_{\mathrm{y}}}, \frac{\varepsilon_{\mathrm{s}}}{\varepsilon}\right)=\eta_{0}(\mathrm{r}) \frac{\left(1+\mathrm{r}^{2} \beta_{\mathrm{x}} / \beta_{\mathrm{y}}\right)}{\left(1+\varepsilon_{\mathrm{s}} / \varepsilon\right)} \tag{11}
\end{equation*}
$$

We can finally write the electric field work as:

$$
\begin{equation*}
\mathrm{W}_{\mathrm{el}} \approx \frac{\mathrm{~m}_{\mathrm{o}} \mathrm{c}^{2} \mathrm{r}_{\mathrm{e}} \mathrm{~N}}{\sigma_{\mathrm{x}}} \sqrt{\eta(\mathrm{r})} \sigma^{\prime} \tag{12}
\end{equation*}
$$

where $\sigma^{\prime}$ is the beam slope at the interaction:

$$
\begin{equation*}
\sigma^{\prime}=\sqrt{\sigma_{\mathrm{x}}^{\prime 2}+\sigma_{\mathrm{y}}^{\prime 2}} \tag{13}
\end{equation*}
$$

## 4. A semi-empirical fit

We come finally to our prediction about the vertical tune shift, through a phenomenological fit of the vertical tune shifts as deduced by the published data.
For each collider and for each different fit we consider the parameter $\lambda_{i}$ defined as:

$$
\begin{equation*}
\lambda_{\mathrm{i}}=\left(\xi_{\mathrm{y}}{ }^{\text {meas }}\right)_{\mathrm{i}} /\left(\xi_{\mathrm{y}}{ }^{\text {fit }}\right)_{\mathrm{i}} \tag{14}
\end{equation*}
$$

The most elementary formula we can think of is a fit with a constant, from which we get the $\xi_{\mathrm{y}}$ value:

$$
\begin{equation*}
\xi_{\mathrm{y}}=\xi_{\mathrm{y}}{ }^{\text {aver }}\left(1 \pm \sigma_{\mathrm{o}}\right) \tag{15}
\end{equation*}
$$

where $\xi_{\mathrm{y}}^{\text {aver }}=0.037$ and $\sigma_{\mathrm{o}}=\left\langle\lambda_{\mathrm{i}}^{2}\right\rangle-\left\langle\lambda_{\mathrm{i}}\right\rangle^{2}=0.274$.

Then we can consider a simple formula as:

$$
\begin{equation*}
\xi_{\mathrm{y}}=\operatorname{cost} \cdot\left(\mathrm{A}_{1}^{\mathrm{e} 1}\right) \cdot\left(\mathrm{A}_{2}{ }^{\mathrm{e} 2}\right) \ldots \ldots \ldots \tag{16}
\end{equation*}
$$

where $\left(\mathrm{A}_{1}, \mathrm{~A}_{2}, \mathrm{~A}_{3}, \ldots.\right)$ are parameters that we choose among the optical parameters of each collider. The exponents ei can be found by applying the least square method to the function:

$$
\begin{equation*}
\mathrm{G}=\Sigma_{\mathrm{i}}\left[\ln \lambda_{\mathrm{i}}\right]^{2} \tag{17}
\end{equation*}
$$

By applying our guiding hypothesis, we should fit $\xi_{\mathrm{y}}$ as:

$$
\begin{equation*}
\xi_{\mathrm{y}}=\operatorname{cost} \frac{\Delta \mathrm{E}_{\mathrm{F}}^{\mathrm{e} 1}}{\mathrm{~W}_{\mathrm{el}} \mathrm{el}^{2}} \tag{18}
\end{equation*}
$$

However there is a disavantage in this formula, since both Wel and $\xi_{y}$ depend on the number of particles $N$. Hence we would have an implicit equation in $N$ or $\xi_{y}$ not suitable for fitting.
We consider then $\xi_{y}$ as a function of parameters as $E, \eta(r), \sigma^{\prime}, \rho_{F}$ and $N_{i}$ that appear in the $\Delta \mathrm{E}_{\mathrm{F}}$ and $\mathrm{W}_{\text {el }}$ formulae. Computing the exponent of each parameter separately we get:

$$
\begin{equation*}
\xi_{y}=5.80 \times 10^{-3} \frac{\mathrm{E}^{.26} \eta(\mathrm{r})^{.54}}{\left(\sigma^{\prime}\right)^{.40} \rho_{\mathrm{F}}^{.23} \mathrm{~N}_{\mathrm{i}} .12} \tag{19}
\end{equation*}
$$

Since the exponent of $\mathrm{N}_{\mathrm{i}}$ is about one half the $\rho_{\mathrm{F}}$ one, namely $\rho_{\mathrm{F}}$ and $\mathrm{N}_{\mathrm{i}}$ act as $\left(\rho_{\mathrm{F}} \sqrt{ } \mathrm{N}_{\mathrm{i}}\right)$, in agreement with our hypothesis on the role of the fluctuations, we can use ( $\rho_{\mathrm{F}} \sqrt{ } \mathrm{N}_{\mathrm{i}}$ ) as an independent variable and we get:

$$
\begin{equation*}
\xi_{y}=5.87 \times 10^{-3} \frac{E^{.27} \eta(\mathrm{r})^{.55}}{\left(\sigma^{\prime}\right)^{.40}\left(\rho_{\mathrm{F}} \sqrt{\mathrm{~N}_{\mathrm{i}}}\right)^{.24}} \tag{20}
\end{equation*}
$$

Eq. (20) also shows the dependence of $\xi$ y on $\sigma^{\prime}$, that we interpret as a negative effect on $\xi_{\mathrm{y}}$ of the electric field. As a comparison, if we consider as an independent variable the contribution from the damping, namely ( $\left.\rho_{D} N i\right)$, where $\rho_{D}=\sqrt{ }\left(2 \pi / I_{2}\right)$, we get instead:

$$
\begin{equation*}
\xi_{y}=5.15 \times 10^{-3} \frac{\mathrm{E}^{.20} \eta(\mathrm{r})^{.48}}{\left(\sigma^{\prime}\right)^{.40}\left(\rho_{\mathrm{D}} \mathrm{~N}_{\mathrm{i}}\right)^{.18}} \tag{21}
\end{equation*}
$$

Let's now compare the results. The goodness of the fit is given by the Snedecor factor: $\mathrm{F}=\left(\sigma_{0} / \sigma^{\text {fit }}\right)^{2}$. Smaller is $\sigma^{\text {fit }}$ with respect to $\sigma_{0}$, larger is $F$ and smaller is the probability P that the choice of the fit parameters is unreliable from a physical point of view. For a comparison, Table 1 reports the values obtained for all the formulae used.

Table 1: Fits comparison

| FORMULA | $\sigma^{\text {fit }}$ | $\mathbf{F}$ | $\mathbf{P}$ |
| :---: | :---: | :---: | :---: |
| $(15)$ | .274 | 1. | .5 |
| $(21)$ | .112 | 5.6 | $3.4 \times 10^{-4}$ |
| $(19)$ | .108 | 6.4 | $2.1 \times 10^{-4}$ |
| $(20)$ | .108 | 6.4 | $1.5 \times 10^{-4}$ |

Formula (20) gives the best fit results.Their values for the considered colliders together with the measured tune shifts and the ratios $\lambda_{i}$ are listed in Table 2.

Table 2: Fit results from formula (20)

In Fig. 1 for each collider the fit results (black triangles) are compared with the measured $\xi_{\mathrm{y}}$ values (white squares).

Figure 1: Comparison of fit and measured tune shifts for flat beams colliders. Machines are listed in order of increasing energy.

If we apply our formula (20) to the DAФNE $\Phi$-factory now under commissioning in Frascati we have: $\left(\xi_{\mathrm{y}}{ }^{*}\right)_{\text {design }}=0.04,\left(\xi_{\mathrm{y}}{ }^{*}\right)_{\mathrm{fit}}=0.049$.

## 5. Discussion

Let's make some remarks on the results of Table 1. The fit with eq. (20) reduces the dispersion on the tune-shift data to $11 \%$ from $27 \%$ of the fit with a constant. Moreover we would like to point out that:

1) the considered parameters range on a large scale: for example between VEPP-2M and LEP the machine radius ranges from 1 m to 2700 m , the energy from .5 GeV to 91 GeV , the number of particles/bunch from $7 . \times 10^{9}$ to $3 \times 10^{11}$.
2) There is a strong dependence on the betatron slope. Without the hypothesis on the work of the electric field this dependence would be unpredictable.
3) The difference in probability and dispersion using the factor $\left(\rho_{\mathrm{F}} \sqrt{ } \mathrm{N}_{\mathrm{i}}\right)$ instead of $\left(\rho_{\mathrm{D}}\right.$ $\mathrm{N}_{\mathrm{i}}$ ) stresses on the role of the fluctuations instead of the damping.
4) The tunes do not appear in eq. (20), since they did not contribute to improve the fit. Our opinion is that the maximum luminosity is reached by experimentally moving the tunes in order to stay far from resonances. At that point the beam-beam limit does not depend anymore on the working point but on other phenomena.
5) Not always maximum tune shift corresponds to maximum luminosity: we want to fit the maximum tune shift, while the published data are often those relative to the luminosity record.

## Acknoledgements

We wish to thank Dr. H. Burkhardt from CERN for kindly providing the LEP data.
