Abstract

At the end of 1995, the Frascati $\phi$-factory will begin delivering of the order of 500 $\phi$-mesons/sec. This provides a unique opportunity to study the $f_0(975)$ in $\phi$ radiative decays, even for branching ratios which in some estimates could be as low as $1 \times 10^{-6}$. This unique, lightest scalar meson state is poorly described by current models, and more information is essential. By Monte Carlo studies we show that the smallest expected branching ratio can easily be measured in the decay $f_0 \rightarrow \pi^0 \pi^0$. In decays to $\pi^+ \pi^-$, there are backgrounds from continuum processes. Interference between one of these processes and the $f_0$ amplitude leads to very interesting and complex patterns. A complete study of the photon spectrum from $e^+ e^- \rightarrow \pi^+ \pi^- \gamma$ at the $\phi$ peak, after suppression of continuum contributions by suitable kinematics and angular cuts, can determine the sign of the $\phi f_0 \gamma$ coupling even for the smallest branching ratio, thus providing a totally new piece of information for the investigation of the nature of the $f_0$. A similar study of the decay $\phi \rightarrow \eta' \gamma$ shows that its branching ratio can be measured with very good accuracy, therefore measuring the gluon contents of light pseudoscalar mesons to high accuracy.

1. INTRODUCTION

DAΦNE,\(^{[1]}\) beginning in 1995, will deliver a luminosity \(\mathcal{L} \sim 10^{32} \text{ cm}^{-2} \text{ s}^{-1}\), yielding of the order of 5 billion \(\phi\)'s in four months of machine-on time: \(5[\mu b] \times 10^{32}[\text{cm}^{-2} \text{ s}^{-1}] \times 10^7 [s] = 5 \times 10^9\). In the following we assume that \(5 \times 10^9 \phi\) mesons are collected in the first year, while DAΦNE is tuned to reach maximum \(\mathcal{L}\). This constitutes an enormously large sample of \(\phi\)'s, previously unavailable, and gives the possibility of detecting rare \(\phi\) decays, especially rare radiative decays which typically are predicted to have branching ratio's (BR) of the order of \(10^{-4}\) to \(10^{-7}\).\(^{[2]}\) Existing experimental measurements are few. The most common radiative mode is \(\phi \rightarrow \eta^0 \gamma\) with BR(\(\phi \rightarrow \eta^0 \gamma\))=0.0128 ± 0.0006; the next most frequent mode \(\phi \rightarrow \pi^0 \gamma\) is measured to an accuracy of only 30%: BR(\(\phi \rightarrow \pi^0 \gamma\))=(0.31±0.13) \times 10^{-3}.\(^{[3]}\) Many modes which are not forbidden by symmetry arguments, but are very interesting from a spectroscopic point of view, such as \(\phi \rightarrow \eta' \gamma\), \(f_0 \gamma\), \(a_0 \gamma\), \(\pi^+\pi^-\gamma\), \(\pi^0\pi^0\gamma\), \(\pi^0\eta\gamma\), have not been observed at all and upper limits of the order of \(10^{-3}\) are given. About the C violating decays \(\phi \rightarrow \omega \gamma\), \(\rho \gamma\), \(\eta \pi^0\) we know nothing; upper limits are of the order of \(10^{-2}\).\(^{[3]}\) We discuss in the following detector issues associated with measuring rare radiative decays amidst prolific background events arising from \(\phi \rightarrow X + \pi^0(\rightarrow 2\gamma)\) decays, with specific examples: \(\phi \rightarrow f_0 \gamma\) and \(\phi \rightarrow \eta \gamma\). We show that background processes, though they might be much larger than the signal, can be well controlled by appropriate kinematical cuts.

For the case of \(f_0 \rightarrow \pi^+\pi^-\), additional backgrounds come from continuum processes such as coupling of the initial \(e^+e^-\) state to the tail of the \(\rho\), an initial state radiation process, and \(e^+e^- \rightarrow \mu^+\mu^-\gamma\) if muons are mistaken for pions. Furthermore, the \(\phi\) can produce a pair of pions through off-shell \(\rho\) production with one of the pions radiating a \(\gamma\), a final state radiation process. We shall call \(A_{\rho}\) the amplitude for this process and \(A_{f_0}\) the amplitude for \(\phi \rightarrow f_0 \gamma \rightarrow \pi^+\pi^-\gamma\).

While initial state radiation only contributes an incoherent background, as it is the only \(\phi \rightarrow \pi\pi\gamma\) process antisymmetric under pion exchange (\(C(\pi^+\pi^-)=-1\)), the amplitudes \(A_{\rho}\) and \(A_{f_0}\) do interfere, because the pions from \(\rho\) decay with final state radiation are in a C-even state, as are those from \(f_0\) decay.\(^{[4,5]}\) The sign of the interference term is unknown, since it depends on the sign of the \(\phi f_0 \gamma\) coupling and therefore on the unknown nature of the \(f_0\).\(^{[2]}\) While the magnitude of final state radiation is approximately one tenth of that for initial state radiation, the \(f_0\) signal is comparable or smaller than the former, by as much as a factor of ten to one hundred. The interference term can drastically alter the \(f_0\) signal in \(\phi\) decays, both in shape and in magnitude. For the
case of destructive interference, the $f_0$ signal can become woefully small, indeed, was expected to essentially disappear in Ref. 5. However, since the shape of the interference term and its angular distributions are different from those from $|A_{f_0}|^2$, the presence of an $f_0$ signal can always be recognized, even when cancellation is maximal. We only lose sensitivity to the presence of $f_0$'s in $\phi$ decays when the branching ratio for $\phi \rightarrow f_0 \gamma$ (BR$_{\phi f_0 \gamma}$) becomes smaller than about $3 \times 10^{-7}$. In addition, the shape of the signal allows in general to determine the sign of the interference term and therefore of the $\phi \rightarrow f_0 \gamma$ amplitude, another valuable piece of information about the poorly-understood $f_0$. The $\mu^+ \mu^- \gamma$ background, while much larger than the signal, can be easily removed in a detector such as KLOE$^6$, by appropriate kinematical cuts. The initial state radiation contribution can be strongly suppressed by angular cuts. Thus we find the conclusions of ref. 5 more pessimistic than necessary.

2. SPECTROSCOPY DETECTORS

2.1 PRECISION EM CALORIMETERS

Spectroscopy requiring detection of neutral particles in the final state has been done in the more recent past with dedicated electromagnetic calorimeters, often composed of scintillating crystals (NaI, BGO, CsI), which give excellent photon energy resolution. Typically a minimal level of tracking with no magnetic field is provided, thus there is no momentum determination for charged particles. This allows to distinguish between charged and neutral particles, and gives the direction of charged particles and the entry point of tracks into the calorimeter. To reconstruct the neutral particles ($\pi^0$, $\eta$ etc.), whose decay products include photons, it is necessary to determine the direction of the final state photons. This is obtained by segmenting the calorimeter into many polar and azimuthal elements to find the electromagnetic (EM) shower centroid to the required accuracy. With highly segmented calorimeters, particle identification is accomplished by recognizing the characteristic energy deposition patterns of particles in the crystals. EM showers from an electron or photon have typical longitudinal and transverse profiles which allow rejection of spurious signals to the $10^{-2} - 10^{-3}$ level. Minimum ionizing particles have constant energy deposition along their paths. Strongly interacting particles, hadrons, may undergo nuclear interactions in the crystals, exhibiting a discontinuous energy deposition pattern at the point of interaction. If the calorimeter is longitudinally segmented finely enough, particle identification can also be aided by
range measurements. The most crucial considerations in obtaining the ideal energy resolution from these calorimeters is to have

1. constant monitoring of the crystal to crystal calibrations, and

2. a precise overall energy scale determination.

The implementation of a neutral particle spectrometer at one of DAΦNE's interaction regions is highly desirable because

1. the luminosity required for spectroscopy studies is less than that required for CP violation studies,

2. neutral particle calorimeters are compact and easier to install and become operational, especially if one transports to DAΦNE a proven world-class spectrometer which can be recycled at the time of DAΦNE's commissioning.

We chose the CUSB-II Spectrometer\(^7\) for our Monte Carlo (MC) feasibility studies of measuring rare radiative \(\phi\) decays at DAΦNE with a neutral particle spectrometer. After the completion of upsilon spectroscopy studies at CESR for a decade, CUSB has been disassembled, packed in crates, stored in toto at the Nevis Laboratories and is available for being reassembled at DAΦNE if needed.

2.2 General Purpose Detectors

These detectors consist of large tracking devices in magnetic field and EM calorimeters inside or outside the coil producing the field. They can measure energy or momenta of charged and neutral particles as well, usually with lower precision for photons, but compensate for this by more complete sensitivity to the full event topology and kinematics. We will also quote in a following section the results of an incomplete MC study of the sensitivity to rare radiative \(\phi\) decay of an operating magnetic spectrometer, the CMD2\(^8\). This spectrometer has its EM calorimeter outside the magnetic coil, resulting in poor energy resolution for low energy photons.

The majority of our results come from simulations in the KLOE detector\(^6\). The detector, surrounding a thin, 10 cm radius beam pipe, consists of a drift chamber with a helium-based gas mixture, of 2 m radius and 4 m length, providing a momentum resolution of \(\sim 0.45\%\), at the range of interest. The chamber is surrounded by a hermetic (solid angle coverage greater than 98\%) electromagnetic calorimeter with three-dimensional readout. The EM calorimeter consists of sandwiches of very thin (0.5mm), grooved, lead foils and 1 mm diameter scintillating fibers. Its energy resolution is \(5\%/\sqrt{E/1\text{GeV}}\),
with full efficiency for 20 MeV photons, and has exceptional timing performance, 300 ps/√(E/20MeV). The angular resolution for photons is excellent, ~±5 mrad.

3. \( \phi \rightarrow f_0 \gamma \)

3.1 \( f_0 \rightarrow \pi^0 \pi^0 \)

We chose for our MC studies the reaction \( \phi \rightarrow f_0 \gamma \), where the \( f_0 \) decays into a \( \pi^+ \pi^- \) pair or into two \( \pi^0 \)’s. The branching ratio for this reaction is interesting because of:

1. the implications it has for the measurement of \( \Re(\epsilon'/\epsilon) \) and \( \Im(\epsilon'/\epsilon) \),

2. the value it has in its own right from a spectroscopic point of view. See the discussion of Brown and Close.\(^{[2]}\)

This decay has not been observed yet. The experimental limit is of the order of \( 2 \times 10^{-3} \), which is much higher than the most optimistic theoretical expectation of \( 2.5 \times 10^{-4} \).\(^{[9]}\) Partial wave analysis suggests that 78% of the \( f_0 \)’s decay to two pions (1/3 neutral, 2/3 charged), 22% to a pair of \( K \)’s.

The signature for the decay \( \phi \rightarrow f_0 \gamma, f_0 \rightarrow \pi^0 \pi^0 \) is five photons, with one of the photons having \( \sim 50 \) MeV and four of the photons reconstructing to a pair of nearly collinear \( \pi^0 \)’s, whose invariant mass sums up to that of the \( f_0 \). The possible background events are from:

1. \( \phi \rightarrow \pi^0 \pi^0 \gamma \), experimentally not yet detected, with an upper limit of \( \text{BR} < 1 \times 10^{-3} \).

   Measured values in this paper are taken from the Particle Data Book\(^{[3]}\) unless otherwise specified. Predicted values for this process via a virtual \( \rho \) vary from \( 1.2 \times 10^{-5} \)\(^{[10,11]}\) to \( 3.62 \times 10^{-5} \).\(^{[12]}\)

2. \( \phi \rightarrow \pi^0 \rho^0 \) with \( \rho \rightarrow \pi^0 \gamma \). The product branching ratio of these two observed processes is \( \text{BR} = (3.4 \pm 0.88) \times 10^{-5} \).

3. \( \phi \rightarrow \pi^0 \rho^0 \) with \( \rho \rightarrow \eta \gamma, \eta \rightarrow 2 \gamma \), with the product \( \text{BR} \) from the three observed processes, \( \text{BR} = (6.4 \pm 1.2) \times 10^{-6} \), all of which yield five photons.

4. \( \phi \rightarrow \gamma \eta \) with \( \eta \rightarrow 3 \pi^0 \), with product \( \text{BR} \) from the observed two processes: \( \text{BR} = (4.1 \pm 2.0) \times 10^{-3} \), and two of the photons are not detected in the calorimeter.

There is no background arising from \( \phi \rightarrow K_S K_L \) where the \( K_S \) decays into \( 2 \pi^0 \)’s and the \( K_L \) decays into \( 3 \pi^0 \)’s and five photons are missed. The (acceptance \( \times K_L \) decay probability) \( \times \text{BR} \), \( A \), in CUSB is \( 5.8 \times 10^{-5} \), in KLOE \( 3.1 \times 10^{-10} \). This is before applying any energy-momentum constraint.
To be on the conservative side, we have considered background (1) both at the estimated level found theoretically in Refs. 10 and 11, and at the much larger level allowed by the current experimental bound. We have treated background (2) separately from background (1) because it can be best dealt with experimentally using the constraint of a physical $\rho$. Moreover, we suspect that the theoretical estimate of background (1) in Refs. 10 and 11 might be low by a factor of two or three since the estimates in the same model for the $\phi \rightarrow \pi^0 \rho^0$ and $\rho \rightarrow \pi^0 \gamma$ branching ratios are also low. $\phi \rightarrow \pi \rho \rightarrow \pi \eta \gamma$ can also be treated similarly as background (1). If we use the theoretical estimate via a virtual $\rho$,[11] (3) is negligible; if we use the experimental value, it is a similar exercise to that of considering background (1).

Using the CUSB Monte Carlo program, signal and background processes were generated and the particles followed through in the CUSB spectrometer. For the $\phi \rightarrow \pi^0 \pi^0 \gamma$ process we have used the matrix elements with angular distributions from reference 10. For completeness of the DAΦNE Physics Handbook, we include them in this paper in the appendix. Photon spectra and acceptance×detection efficiencies ($\epsilon$) for each process were obtained after applying the following selection criteria: five and only five photons are present in the detector; four of the photons are paired into two $\pi^0$'s whose reconstructed mass must be within 50 MeV of the $\pi^0$ mass; the reconstructed $f_0$ mass from the two pions must be within 50 MeV of the expected mass peak at 975 MeV; the energy of the leftover photon is to be less than 95 MeV, and, finally, the invariant mass of all the decay products must be within 50 MeV of the known $\phi$ mass. $\epsilon$ for the signal in CUSB is $(9.7 \pm 0.1) \times 10^{-2}$. This small CUSB value arises from the fact that CUSB central calorimeter covers a solid angle of $0.7 \times 4\pi$, which results in a geometrical acceptance for five photons of 0.17 (to be contrasted with KLOE which covers over 98% of $4\pi$, thus resulting in a geometrical acceptance for five photons of 0.92). The application of kinematical cuts, reconstruction of pions, and $f_0$, etc., account for the rest of the loss. CUSB has superb photon energy resolution, which is given by $\sigma(E_{\gamma})/E_{\gamma} = 2\%/\sqrt{E_{\gamma}}$ where $E_{\gamma}$ is measured in GeV. The compensation for applying all the selection criteria in CUSB is that the $\epsilon$'s for backgrounds 1–3 are down by about a factor of 42, and, background (4) is negligible. Table la summarizes the experimental numbers.

All spectra of background photon surviving the cuts were fitted to polynomials, $g(k)$ where $k$ is the photon energy. The signal can be fitted to a Breit-Wigner form, $s(k)$. Using the a priori error estimate,[13] the fractional accuracy of the signal BR is given by:

$$\frac{\delta(BR)}{BR} = \frac{1}{BR} \frac{1}{\sqrt{N}} \left( \int \frac{1}{f(k)} \left( \frac{\partial f(k; BR)}{\partial BR} \right)^2 dk \right)^{-\frac{1}{2}}$$  \hspace{1cm} (3.1)

where

$$f(k) = \sum_{i=1}^{4} \epsilon_{\text{bcknd},i} \times BR_{\text{bcknd},i} \times g_i(k) + \epsilon_{\text{signal}} \times BR_{\text{signal}} \times s(k).$$

Thus, in a year’s run at DAΦNE (~5×10^9 $\phi$’s), CUSB can measure BR($\phi \rightarrow f_0 \gamma$) using the two $\pi^0 \pi^0$ decay mode, from 0.4% to 14% accuracy over the expected range of theoretical predictions if the BR for direct $\phi \rightarrow \pi^0 \pi^0 \gamma$ is the one expected theoretically. If the direct $\phi \rightarrow \pi^0 \pi^0 \gamma$ BR is at the experimental limit the smallest BR$_{\phi f_0 \gamma}$ that CUSB can measure to 5 sigma accuracy is 1.0×10^{-6}, which means that any good spectrometer can access the smallest branching ratio. These results are tabulated in Table Ib.

Applying the same selection criteria in KLOE, the loss in signal is much less severe, because for this particular decay involving five photons from a wide parent signal ($f_0$) peak, it is more important for kinematical fitting and reconstruction to have small photon losses than extremely precise energy resolution.

The efficiencies in KLOE for the $f_0$’s neutral decay mode is estimated to be 84%, 30 times better than CUSB.[14] The accuracy attainable by KLOE in the same corresponding period is shown in the last column of table Ib. One expects superb sensitivities to the signal over the whole range of signal and background BR’s examined.

Fig. 1 shows the photon spectrum in CUSB from one year's run with BR($\phi \rightarrow f_0 \gamma$) = 2.5\times10^{-4} and BR($\phi \rightarrow \pi^0 \pi^0 \gamma$) = 1\times10^{-3}.

![Graph showing photon spectrum](image-url)

**Figure 1.** Photon Spectrum (Signal + Background) in CUSB from $\phi \rightarrow f_0 \gamma$.

3.2 $f_0 \rightarrow \pi^+ \pi^-$

3.2.1 Backgrounds from misidentified $\phi$ decays

The signature for $\phi \rightarrow f_0 \gamma$, $f_0 \rightarrow \pi^+ \pi^-$ is a pair of nearly collinear charged pions, whose invariant mass equals that of the $f_0$, and one low energy photon. The possible
backgrounds from misidentified φ decays are

1. φ→π⁺π⁻π⁰, BR=(1.9±1.1)×10⁻².
2. φ→π⁰ρ⁰→π⁰π⁺π⁻, product BR=(4.3±0.2)×10⁻².
3. φ→π⁺ρ⁻→π⁰π⁺π⁻, product BR=(8.6±0.5)×10⁻².

These reactions yield two oppositely charged pions and one neutral pion, so contribute to the background if one photon is not detected.

There is no background arising from φ→KₖKₗ where the Kₖ→π⁺π⁻ and Kₗ→3π⁰’s and five photons are not detected. A for CUSB is of the order of 1.2×10⁻⁵, and for KLOE it is 1.7×10⁻¹¹. Nor is there from φ→KₖKₗ where Kₖ→π⁰π⁰ and Kₗ→π⁺π⁻π⁰ or π⁺μ⁻ν, and five or three photons are undetected. A for CUSB is of the order of 3.3×10⁻⁶ and 5.3×10⁻⁵ for the two processes; for KLOE the corresponding A’s are 4.5×10⁻¹² and 5.4×10⁻⁸. Finally, there is also no background arising from φ→KₖKₗ where the Kₖ→π⁺π⁻ and Kₗ→γγ and one photon is not detected. A for CUSB is of the order of 1.4×10⁻⁶, for KLOE 1×10⁻⁶. All these numbers are obtained before applying the energy-momentum conservation constraint.

Again, signal and background processes were simulated in the CUSB spectrometer. We used the following selection criteria: two tracks and one photon are present in the detector; the opening angle between the two tracks is within 2° of 175°; the energy of the photon is within 10 MeV of 53 MeV. Table IIa summarizes the BR’s and ε’s for the background processes and the signal, for the three detectors. Table IIb gives the fractional error in measuring the signal BR, calculated as in the previous section.

In this decay again CUSB suffers from lack of hermeticity, as well as lack of momentum information. Thus, the dominant background comes from the πρ final states, which give π⁺π⁻π⁰ where one of the photons escape the detector. We cannot use energy-momentum constraints and select by mass cuts the signal due to a real ρ being produced. The complete KLOE simulation is still in progress. However, because of
KLOE's hermeticity, and the fact that one measures the charged particles' momenta, applying kinematical constraints and cuts around the \( \rho \) mass make background processes (1), (2) and (3) practically negligible despite their larger BR's. The KLOE column in tables IIa and IIb are obtained by using KLOE's geometry and assuming 0.45\% momentum resolution. The fractional accuracy achievable has been increased by a factor two, to roughly account for various uncertainties not yet fully evaluated. Similar results were reported by the CMD2 Detector\(^8\) which is also supposed to be hermetic. While its momentum resolution and energy resolution are a factor of two worse than KLOE's, for this signal this is not important because of the width of the \( f_0 \). So, in conclusion, if these were the only backgrounds, using general purpose detectors, the photon contamination from the background in the signal region disappears, and one could expect a very good BR determination over the whole range of signal and background BR examined.

However, we shall see in the next sections that other backgrounds (notably from initial and final state radiation) are by far dominant. Since the misidentified \( \phi \) decay background already essentially disqualifies CUSB for this process, we will present the rest of our simulations in the detector KLOE.\(^{15}\)

### 3.2.2 Backgrounds from \( e^+e^- \rightarrow \mu^+\mu^-\gamma \)

The cross section at 1020 MeV for \( e^+e^- \rightarrow \mu^+\mu^-\gamma \), where the photon energy is between 10 and 120 MeV, is 4.8 nb, equivalent to a BR of \( 1 \times 10^{-3} \), orders of magnitude larger than the signal from \( f_0 \rightarrow \pi^+\pi^-\gamma \) whose BR is at most \( 1.3 \times 10^{-4} \).\(^{16}\) The large background contribution from \( e^+e^- \rightarrow \mu^+\mu^-\gamma \) can however be fully controlled in KLOE because of its good momentum resolution.

While the calorimeter resolution at low energies is relatively poor, events with two charged particles and a photon are four times overconstrained. For \( \phi \) production at rest, momentum conservation gives \( E_\gamma = |p^+ + p^-| \). From energy conservation, assuming that the positive and negative particles are pions, we get \( E'_\gamma = M_\phi - E^+ - E^- \). For \( \phi \rightarrow \pi^+\pi^-\gamma \) we expect \( E_\gamma = E'_\gamma \), while for \( e^+e^- \rightarrow \mu^+\mu^-\gamma \), the two energies differ by about 17.5
MeV, having used the pion mass for the muons. We have generated by Monte Carlo (MC) simulations the difference $\Delta E_\gamma = E_\gamma - E'_\gamma$, using the expected KLOE momentum resolution.\cite{5} For $\phi \to \pi^+\pi^-\gamma$ decays we find that the rms spread of $\Delta E_\gamma$ is 2 MeV and for $e^+e^-\to \mu^+\mu^-\gamma$, $\Delta E_\gamma = 17.5$ MeV, also with a spread of 2 MeV. Therefore, a cut at in $\Delta E_\gamma$ at 8 MeV gives us a rejection factor of $\sim 2400$ against the muon background, which in fact makes it negligible with respect to any other processes with pions in the final states. Note that we have not used the well measured photon direction ($\pm 5$ mrad) for additional help.

3.2.3 Backgrounds from $e^+e^-\to \pi^+\pi^-\gamma$

As we have seen in the previous sections, the background from misidentified events can be completely controlled in KLOE if we select $f_0$ candidates by requiring that only a pair of nearly collinear, oppositely charged tracks and one low energy photon, $20 < E_\gamma < 100$ MeV, are present in the detector; that the visible energy equals $W$, the total energy, and that $\Delta E_\gamma < 8$ MeV, in order to eliminate the $\mu^+\mu^-\gamma$ background.

In the remainder of this chapter, we discuss the various contributions to the final physical state $\pi^+\pi^-\gamma$ from $e^+e^-$ annihilation at the $\phi$ peak. Four amplitudes, $A_1$, $A_2$, $A_{\rho^*}$ and $A_{f_0}$, contribute. The corresponding intensities, $|A_1|^2$, $|A_2|^2$ and $|A_{\rho^*}|^2$ are background contributions and the $f_0$ signal is contained in $|A_{f_0}|^2$ and $2\Re(A_{\rho^*}A_{f_0}^*)$, as discussed below.

- $A_1 = A(\phi \to \pi_1\rho^* \to \pi_1\pi_2\gamma)$. This is the amplitude for $\phi \to \pi^+\pi^-\gamma$ via $\pi\rho^*$ with the $\rho^*$ coupling to $\gamma\pi$. $\rho^*$ here stands for an internal line, virtual $\rho$ in the corresponding Feynman amplitude. The Feynman diagram for this process is shown in Fig. 2a. We have already discussed the analogous process for neutral pions in Sec. 3.1. Its contribution to the background is small compared to the other sources, see Fig. 3a. In this figure we have taken $A_1$ at its theoretically estimated level,\cite{10,11} but we have checked\cite{17} that even if we take it at the experimental upper limit, the changes in our results are negligible. The angular dependence of $A_1$ is shown in Fig. 12. The interference of this background with other processes is also negligible.

- $A_2 = A(e^+e^-\to \gamma\gamma \to \rho^*\gamma \to \pi^+\pi^-\gamma)$. The Feynman diagram for this process is shown in Fig. 2b. This amplitude from initial state radiation is the largest incoherent source of background. However, since, as expected for a radiative process, and seen in Fig. 13, $|A_2|^2$ is peaked very sharply at small angles between the photon and the beam, $\theta_{\gamma,\text{beam}}$, we reduce its contribution by a factor of $\sim 7$ by a cut $|\cos \theta_{\gamma,\text{beam}}| < 0.9$, see
Fig. 2. The Feynmann diagrams of the processes discussed in the text.

- $A_{\rho^*} = A(\phi \rightarrow \rho^* \rightarrow \pi^+ \pi^- \gamma)$, the $\gamma$ being radiated from one of the pions. The Feynman diagram for this process is shown in Fig. 2c. This process contributes approximately one tenth of the $A_2$ background. However, as expected for a radiative process and seen in Fig. 14, $|A_{\rho^*}|^2$ is peaked at small values of the angle between the pions and the photon in the dipion rest frame, $\theta_{\pi\gamma}$. We therefore restrict $|\cos \theta_{\pi\gamma}|$ to be less than 0.9, see Fig. 3c. The sum of these three sources of background is shown in Fig. 3d, the solid line being without angular cuts, the dashed line with the two angular cuts of $|\cos \theta|$ less than 0.9. With these cuts combined, we retain 80% of the signal and improve the signal to background ratio, $S/B$, by a factor of 5 - 6, see Figs. 8 and 9.

- $|A_{f_0}|^2$ and $2\Re(A_{\rho^*}A_{f_0}^*)$. The Feynman diagram for the signal process $\phi \rightarrow f_0 \gamma$ is shown in Fig. 2d. The angular dependence of $|A_{f_0}|^2$ is $(1 + \cos^2 \theta_{\gamma, \text{beam}})$, as seen in Fig. 15. The amplitude given in Ref. 5 ignores the bound quark pair wave function of the corresponding mesons, without which the amplitude blows up because of the $k^3$ factor characteristic of the emission of a photon of momentum $k$. We damp the amplitude following De Rújula, Georgi and Glashow$^{[18]}$ with an exponential $A e^{-\gamma/\Gamma}$.
where $x = s - M_{\pi \pi}^2 = 2m_\phi E_\gamma$, $\Gamma = 300$ MeV, and $A=2.65$ normalizes the damping factor to 1 at the $f_0$ peak (42.7 MeV). The signal size depends on BR_{\pi f_0 \gamma}. We illustrate it for the two extremes of the range of interest, in Figs. 4a and 5a. We use 52% for BR($f_0 \rightarrow \pi^+ \pi^-$).
Figure 4. a. $\gamma$ spectrum: $f_0 \rightarrow \pi^+\pi^-\gamma$; b. $2\Re(A_{\rho^+}A_{\rho^+}^*)$; c. $|A_{f_0}|^2 - 2\Re(A_{\rho^+}A_{\rho^+}^*)$; d. $|A_{f_0}|^2 + 2\Re(A_{f_0}A_{f_0}^*)$. BR$_{\phi f_0 \gamma} = 1 \times 10^{-6}$. Solid lines are without angular cuts, dotted lines are for $|\cos \theta_{\gamma, \text{beam}}| < 0.9$ and $|\cos \theta_{\gamma} < 0.9$.

The interference term $2\Re(A_{\rho^+}A_{\rho^+}^*)$ is slightly peaked along the beam direction and slightly suppressed along the pions, seen in Fig. 16 in the appendix. Its integrated magnitude is shown for the two extreme cases of the BR$_{\phi f_0 \gamma}$ in Figs. 4b and 5b. For small BR$_{\phi f_0 \gamma}$ the interference term dominates in absolute value over the $f_0$ term, while the reverse is true for the largest BR$_{\phi f_0 \gamma}$. This interesting cross over is because $|A_{f_0}|^2$ is
Figure 5. a. $\gamma$ spectrum: $f_0 \rightarrow \pi^+ \pi^- \gamma$; b. $2\Re(A_{\rho^*}A_{f_0}^*)$; c. $|A_{f_0}|^2 - 2\Re(A_{\rho^*}A_{f_0}^*)$; d. $|A_{f_0}|^2 + 2\Re(A_{\rho^*}A_{f_0}^*)$. BR$_{\phi f_0 \gamma} = 2.5 \times 10^{-4}$. Solid lines are without angular cuts, dotted lines are for $|\cos \theta_{\gamma, \text{beam}}| < 0.9$ and $|\cos \theta_{\gamma}| < 0.9$.

proportional to BR$_{\phi f_0 \gamma}$, whereas the interference term varies as $\sqrt{\text{BR}_{\phi f_0 \gamma}}$. Thus, even for destructive interference, the contribution of $|A_{f_0}|^2 + 2\Re(A_{\rho^*}A_{f_0}^*)$ to the total cross section is not always negative. Figs. 4c,d and 5c,d show $|A_{f_0}|^2 \pm 2\Re(A_{\rho^*}A_{f_0}^*)$ for the two extremes of the range of interest. For BR$_{\phi f_0 \gamma} \sim 1.75 \times 10^{-4}$, the integrated contribution to the $\pi^+ \pi^- \gamma$ cross section vanishes; however, a dip appears at low $\gamma$ energies and an
enhancement at high $\gamma$ energies, allowing detection of the $f_0$ signal.

The angular dependence of $|A_{f_0}|^2 + 2\Re(A_{\rho^*}A_{f_0}^*)$ also depends on the relative strength of each term, of course reflecting that of the dominant one. To illustrate the complexity of the situation, we choose $\text{BR}_{\phi f_0 \gamma} = 1.5 \times 10^{-4}$, where the two terms have about equal strength, and show $d^2\sigma / dE_\gamma d\cos \theta_{\gamma, \text{beam}}$ vs $E_\gamma$, $\cos \theta_{\gamma, \text{beam}}$, and $d^2\sigma / dE_\gamma d\cos \theta_{\pi\gamma}$ vs $E_\gamma$, $\cos \theta_{\pi\gamma}$ for constructive interference in Figs. 6a and b respectively. The same quantities in the case of destructive interference are shown in Figs. 7a and b respectively, where dips and enhancements are clearly visible. We also note that the relative strength of $|A_{f_0}|^2$ and $2\Re(A_{\rho^*}A_{f_0}^*)$ are modulated by the $\gamma-\pi$ angle, upon which $A_{\rho^*}$ depends strongly.

For $\text{BR}_{\phi f_0 \gamma} = 1 \times 10^{-6}$, the signal over the background cannot be shown directly. In order to demonstrate the effectiveness of the cuts we show the signal to background (S/B) ratio for the two cases of constructive and destructive interference, Figs. 8a,b. Note that in both cases we enhanced this ratio by about a factor of five, for a net effect of a few $\%$, for either destructive or constructive interference. With the expected DA$\Phi$NE luminosity the signal is quite measurable. In Figs. 8c,d we show the S/B for $\text{BR}_{\phi f_0 \gamma} = 2.5 \times 10^{-4}$. The signal is certainly much larger and should be much easier to measure.

Fig. 9 shows the MC simulated photon spectrum which would be observed in KLOE (after cuts) for $\phi \rightarrow f_0 \gamma \rightarrow \pi^+\pi^-\gamma$ for the two cases, constructive and destructive interference, for $\text{BR}_{\phi f_0 \gamma} = 2.5 \times 10^{-4}$ and assuming $5 \times 10^9 \phi$'s are produced in the first year of DA$\Phi$NE's operations. The incoherent background contribution is also shown. In Fig. 10 we show the resultant estimate of the fractional accuracy that KLOE can achieve in one year's running at DA$\Phi$NE, which gives pleasant reassurance that even at the smallest $\text{BR}_{\phi f_0 \gamma}$ considered and with destructive interference, the fractional accuracy in the measurement of BR is ten percent. In addition we note that the differential rate $d^3\Gamma / dE_\gamma d\cos \theta_{\gamma, \text{beam}} d\cos \theta_{\pi\gamma}$ clearly contains more information than the integrated cross section, thus it is possible to improve on the results presented. The study of $\phi \rightarrow f_0 \gamma \rightarrow \pi^0\pi^0\gamma$ provides an independent measure of the strength of the $\phi f_0 \gamma$ coupling and therefore a check on the determination of its sign in the $\pi^+\pi^-$ case, thus completing the picture of the $f_0$.

Figure 10. Fractional error on BR$_{\phi/\gamma}$ vs BR$_{\phi/\gamma}$. Solid line is for destructive interference, dashed line for constructive interference.
4. $\phi \to \eta'\gamma$

We have also studied the accuracy achievable by KLOE in the measurement of $\text{BR}(\phi \to \eta'\gamma)$, for an equal running period. This $\phi$ decay mode has never been seen; the experimental upper limit is $4.1 \times 10^{-4}$. Measurement of the BR of this mode will shed light on the gluonium content, $Z_{\eta'}$, of the $\eta'$. The rate for radiative decays of the $\phi$ to pseudoscalar mesons containing $\bar{s}s$ pairs is proportional to the amplitude, $Y$, of the $\bar{s}s$ component of their wave function, giving the scaling law:

$$\frac{\Gamma(\phi \to \eta'\gamma)}{\Gamma(\phi \to \eta\gamma)} = \left( \frac{Y_{\eta'}}{Y_{\eta}} \right)^2 \left( \frac{k_{\eta'}}{k_{\eta}} \right)^3 \sim 4.6 \times 10^{-3} \left( \frac{Y_{\eta'}}{Y_{\eta}} \right)^2.$$  (4.1)

To give an idea of the expected order of magnitude of the branching ratio, for $Z_{\eta'} = 0$ and the $\eta - \eta'$ mixing angle $\theta_p = -20^\circ$, $\text{BR}(\phi \to \eta'\gamma) \sim 1.2 \times 10^{-4}$.

The signature for $\phi \to \eta'\gamma$, $\eta' \to \pi^+\pi^-$ and $\eta \to \gamma\gamma$ is: a pair of charged pions, two photons whose invariant mass equals that of the $\eta$, and one low energy photon. The invariant mass of all particles must equal the $\phi$ mass. By applying these criteria, the efficiency $\times$ acceptance for the signal in KLOE is 74.5%. The possible background events are from:

1. $\phi \to \eta\gamma$, BR=$(1.28 \pm 0.06) \times 10^{-2}$, $\eta \to \pi^+\pi^-\pi^0$, product BR $3.0 \times 10^{-3}$. Use of kinematical constraints pushes the background down so that the efficiency $\times$ acceptance for this background in KLOE is $2.6 \times 10^{-3}$.

2. $\phi \to \omega\gamma$, BR$<5\%$, $\omega \to 3\pi$, product BR$=4.4 \times 10^{-2}$. After kinematical constraints, one finds an efficiency $\times$ acceptance for this background in KLOE of $5.9 \times 10^{-3}$.

3. $\phi \to \pi^0\rho^0 \to \pi^0\pi^+\pi^-$, product BR=$(4.8 \pm 0.6) \times 10^{-3}$. Overall kinematical constraints again result in an efficiency $\times$ acceptance for this background in KLOE of $5.6 \times 10^{-3}$.

We can calculate in this way the fractional accuracy achievable in KLOE for the measurement of this BR. The results are tabulated in table III. In Fig. 11 we show the resultant $\gamma$ spectrum in KLOE. We note that in the first year's run, KLOE can measure BR's of $\sim 1\%$ of the value in eq. 4.1, for zero gluon content.

5. CONCLUSION

We have studied the experimental problems associated with measuring $\phi$ radiative decays by choosing two typical and interesting ones: $\phi \rightarrow f_0\gamma$, where the $f_0$ decays to two neutral pions or two charged pions, and $\phi \rightarrow \eta'\gamma$. We simulated the signal and the expected background in a neutral particle spectrometer: CUSB-II found the decay to neutral pions easily measurable in one year's running time ($\sim 5 \times 10^9$ $f^{'s}$). We also made estimates for the case of two general purpose detectors: KLOE and CMD2, and found the hermeticity of these detectors render the measurements almost trivial. However, the charged pion mode is subject to further background that can only be controlled in a hermetic detector. We found that despite possible destructive interference between the signal and final state radiation, and a large incoherent background from initial state radiation, by using the charged pions, KLOE will be able to determine the sign of the interference, and the magnitude of BR$_{\phi f_0\gamma}$ to accuracies ranging from a fraction of a percent to at most 10 percent in the worst case. The study of $\phi \rightarrow f_0\gamma \rightarrow \pi^0\pi^0\gamma$ provides an independent measure of the strength of the $\phi f_0\gamma$ coupling and therefore a check on the determination of its sign in the $\pi^+\pi^-$ case, thus completing the picture.
of the $f_0$. We found the $\eta'$ search using KLOE relatively easy. Implementation of both types of detectors at DA$\Phi$NE is highly desirable and promises to produce good physics.

6. APPENDIX

For completeness, in this Appendix we give the full angular distributions of the $\phi$ decay to $\pi\pi\gamma$ through a virtual $\rho$, in other words, the matrix element resulting from calculating the Feynman diagrams starting with $e^+e^-$ rather than with a resonance in an averaged polarization state. This yields the same integrated rates as found previously \cite{Bramon} but, in addition, the correct angular distributions, which are necessary for Monte Carlo simulations of these processes.

In general, the full angular dependence of a $\phi$ decay process, where the $\phi$ originates in an $e^+e^-$ collision, can be derived by replacing the $\phi$ polarization vector $\epsilon_\mu$, in an amplitude given for $\phi$ decay, by $\epsilon_{\gamma\mu}e$, or, if

$$A(\phi \to XYZ) = \epsilon_{\mu}^* R_{\mu}$$

we have

$$|A(e^+e^- \to \phi \to XYZ)|_{e^+e^- \text{ spin avg.}}^2 = (p_\mu^\nu p'^\nu + p'^\mu p_\mu - g_{\mu\nu} p \cdot p') R_{\mu} R_{\nu}$$

where $p$ and $p'$ are the electron and positron 4-momenta. Thus, the decay width of a $\phi$ originating in $e^+e^-$ collisions is:

$$d\Gamma(\phi e^+e^- \to XYZ) = d\sigma(e^+e^- \to \phi \to XYZ) \frac{\Gamma(\phi \to \text{everything})}{\sigma_{\text{prod}}(e^+e^- \to \phi)} = \frac{K|A|^2}{M_\phi^2},$$

where $K$ is the usual kinematic factor for decays,

$$K = \frac{1}{64\pi^3} \frac{1}{M_\phi^2} dE_1 dE_2 \frac{d\phi_1}{2\pi} \frac{d\phi_2}{2\pi}$$

with an extra factor of 1/2 if there are two identical particles in the final state. The point of this notation is to isolate the changes needed to go from previous calculations to ones taking into account the $\phi$ polarization when produced in $e^+e^-$ collision. These are simply: changing from eq. (6.1) to (6.2); the factor of $\frac{1}{M_\phi^2}$ in eq. (6.3), and the missing polarization averaging factor of $\frac{1}{4}$ in eq. (6.4).

We then have, for $\phi \to \rho \pi \pi$ and $\pi^+\pi^-\gamma$

$$R_{\mu} = \left( \frac{\epsilon G^2 e}{3g\sqrt{2}} \right) \frac{\epsilon_{\mu\alpha\beta\gamma}(q_\alpha + p_\alpha^+)q_{\beta}^* \epsilon_\gamma q_\delta(q_\epsilon + p_\epsilon^+)\epsilon_\rho}{M_\rho^2 - (q + p^+)^2 - iM_\rho \Gamma_\rho} + (p^+ \leftrightarrow p^-)$$

where $G = (3\sqrt{2}g^2)/(4\pi^2 f_\pi)$, $f_\pi$ is the pion decay constant, 132 MeV, $g=4.2$, and $\epsilon = -0.059$ (see Ref. 11 for further details).
The most compact way to display our result, then, is to borrow the notation of Creutz and Einhorn,\textsuperscript{[4]} correcting a factor of 1/2 and some signs that we find ourselves in disagreement with (we have subsequently confirmed with the authors that these differences were previously unnoticed typographical errors in their published paper):

$$
|A|^2 = \left( \frac{eG_{\pi}}{3g\sqrt{2}} \right)^2 s^2 \left[ \frac{1}{2} |H_1|^2 \beta_\pi^2 t \sin^2 \theta_\pi \sin^2 \theta_\pi \gamma + \frac{1}{2} |H_2|^2 \beta_\pi^4 t \sin^2 \theta_\pi \gamma \\
\times \left( \cos^2 \theta_\pi \gamma + \frac{t}{s} \sin^2 \theta_\pi \gamma - (\cos \theta_\gamma \cos \theta_\pi \gamma - \frac{t}{s} \sin \theta_\gamma \sin \theta_\pi \gamma \cos \phi) \right) \right] + |H_3|^2 (1 + \cos^2 \theta_\pi)/(2s) \\
+ \text{Re}(H_1 H_2^*) \beta_\pi^3 t \sin \theta_\gamma \sin^2 \theta_\pi \gamma \left( \sqrt{\frac{t}{s}} \sin \theta_\pi \gamma \cos \theta_\gamma \cos \phi + \sin \theta_\gamma \cos \theta_\pi \gamma \right) \\
+ \text{Re}(H_1 H_3^*) \beta_\pi \sqrt{\frac{t}{s}} \sin \theta_\gamma \cos \theta_\pi \gamma \sin \theta_\pi \gamma \cos \phi + \text{Re}(H_2 H_3^*) \beta_\pi^2 \sqrt{\frac{t}{s}} \sin \theta_\pi \gamma \\
\times \left( \sin \theta_\gamma \cos \theta_\pi \gamma \cos \phi + \sqrt{\frac{t}{s}} \sin \theta_\pi \gamma (1 - \sin^2 \theta_\gamma \cos^2 \phi) \right). 
$$

(6.6)

where $t$ is the four-momentum squared of the dipion system, $s$ of the dilepton system, and $\beta_\pi$ the velocity of the pions in the dipion rest frame, $\beta_\pi = \sqrt{1 - \xi/(1 - x)}$. $\phi$ is the angle between the $e^+e^-\gamma$ plane and the $\pi^+\pi^-$ plane in the lab frame or the dipion rest frame; $\theta_\gamma$ is the photon-beam angle in the lab frame, and $\theta_\pi \gamma$ is the angle between the pions and the photon in the dipion rest frame related to the pion energy $E_\pi$ in the lab frame by

$$
y = 1 - \frac{x}{2} \left( 1 + \cos \theta_\pi \gamma \sqrt{1 - \frac{\xi}{1 - x}} \right). 
$$

(6.7)

where $x = 2E_\gamma/\sqrt{s}$, $y = 2E_\pi/\sqrt{s}$, and $\xi = 4m_\pi^2/\sqrt{s}$. $E_\gamma$ and $E_\pi$ are the energies of the photon and one of the pions in the lab frame. The $H_i$ are general form factors which in our case are given by

$$
H_i = \frac{h_i}{M_\rho^2 + 2M_\rho E_\pi - M_\pi^2 - m_\pi^2 - iM_\rho \Gamma_\rho} + (\pi^+ \leftrightarrow \pi^-) 
$$

(6.8)

with

$$
h_1 = -\frac{sx}{8}, h_2 = \frac{sx}{8}, h_3 = \frac{s^2}{8} (2x^2 + x\xi - 2x - 2y^2 + 2y). 
$$

(6.9)

The $h_i$ and $h_i(\pi^+ \leftrightarrow \pi^-)$ come from the direct and crossed diagrams, and the separate contributions from these diagrams and their interference may be easily written in terms of the $h_i$. Combining all these equations then gives the full angular dependence for $\phi_{e^+e^-} \rightarrow \pi^+\pi^-\gamma$ via a virtual $\rho$; $\phi_{e^+e^-} \rightarrow \pi^0\pi^0\gamma$ is identical except for the factor of 1/2.
in \( \mathcal{K} \). The angle \( \phi \) can be trivially integrated over by replacing \( \cos^2 \phi \) by \( \frac{1}{2} \), and \( \cos \phi \) by zero (after first expanding the squared expression in the second line of the above equation).

In Fig. 12a,b we show two views of the angular distribution: \( \frac{d^2 \sigma}{dE_\gamma d \cos \theta_{\gamma,\text{beam}}} \) vs \( E_\gamma \), \( \cos \theta_{\gamma,\text{beam}} \), and \( \frac{d^2 \sigma}{dE_\gamma d \cos \theta_{\pi \gamma}} \) vs \( E_\gamma \), \( \cos \theta_{\pi \gamma} \) for \( \phi^+ \phi^- \rightarrow \rho \pi \rightarrow \pi^0 \pi^0 \gamma \). The angle \( \theta_{\pi \gamma} \) used here is the angle between the pions and the photon in the dipion rest frame. For the completeness of the DAΦNE handbook we also include the same views for the other processes considered in this paper: in Fig. 13, initial state radiation; in Fig. 14, final state radiation; in Fig. 15, the signal process, \( \phi \rightarrow \phi_0 \gamma \rightarrow \pi^+ \pi^- \gamma \); and in Fig. 16, the interference between signal and final state radiation.

ACKNOWLEDGEMENTS

We wish to thank Paolo Franzini for discussions and help in preparing this paper.
