1. - INTRODUCTION -

The amount of experimental data on single photoproduction process is at present sufficiently large for \( \pi^+ \) and \( \pi^0 \) photoproduction on protons and the phenomenological analysis of these reactions is rather satisfactory in the low energy range. On the contrary the experimental data for \( \pi^- \) photoproduction on neutrons are, in this respect, still insufficient and, moreover, the use of deuteron as a target makes some authors doubt the interpretation of the few results available.

In the present paper we report the results of an experimental investigation of the reaction

\[
\gamma + n \rightarrow p + \pi^-
\]

up to 1 GeV, performed at the Frascati Electron-Synchrotron with deuterium bubble chamber.

(+): Istituto di Fisica dell'Università, Napoli - Istituto Nazionale di Fisica Nucleare, Sezione di Napoli.

(o): Istituto di Fisica dell'Università, Pavia - Istituto Nazionale di Fisica Nucleare, Sezione di Pavia.

(x): Istituto di Fisica dell'Università, Roma - Istituto Nazionale di Fisica Nucleare, Sezione di Roma.
In the preliminary results(1) we observed some remarkable differences between the proton and neutron total cross-sections in the so-called second resonance region (600 - 800 MeV), suggesting the presence of different resonant contributions in the two channels. The different position of the bump in the total cross-sections and the results of a simplified phenomenological fit of the angular distributions indicated the presence of a $P_{11}$ (1470) contribution larger than that of the $D_{13}$ (1520), which dominates the $\pi^+$ photoproduction process in the same energy region.

This fact, if confirmed, has some nontrivial consequences on the problem of the classification of resonances in the SU$_3$ - scheme.

Moreover the comparison of $\pi^+$ and $\pi^-$ total cross-sections in the first resonance region may indicate the presence of an isotensor part in the electromagnetic current. Finally, the comparison between the results of reaction (1) and of the inverse one ($\pi^+$ radiative capture) may give a direct information about the time-reversal properties of the electromagnetic interactions.

Clearly a detailed investigation of the reaction (1) is important not only in view of phenomenological description of the photoproduction processes but also for the more general questions which are involved. The present paper is divided into six sections. In Sect. 2 the experimental procedure is briefly described. In Sect. 3 the problem of the use of the deuteron as a target is considered in detail. In Sect. 4 the total and differential cross-sections are presented. In Sect. 5 some considerations on the results concerning the possible $T$ - violation and isotensor current contribution, a phenomenological fit to the differential cross-sections and the $P_{11}$ (1470) photoproduction, are reported. Conclusions are given in Sect. 6.

2. - EXPERIMENTAL APPARATUS AND PROCEDURE -

We have analyzed 500,000 pictures obtained by exposing the CERN 30 HBC, (suitably modified in order to run with Deuterium), to the hardened 1 GeV bremsstrahlung beam at the Frascati Electron-Synchrotron.

The experimental lay-out is the same as in a foregoing experiment(2).

The photon flux and the photon spectrum were determined by counting and measuring a sample of $e^+e^-$ pairs in the fiducial volume of the chamber. In fig. 1 the measured spectrum is shown.

The actual measured reaction is $\gamma + d \rightarrow p_s + p + \pi^-$, where $p_s$ is the spectator proton, which is assumed to be the one with the lo-
wer momentum. The events were fitted kinematically with three constraints. When the spectator proton was not visible \((p_S \approx 80 \text{ MeV/c})\), the usual assumption was made:

\[
p_x = p_y = p_z = 0 \quad \text{and} \quad \Delta p_x = \Delta p_y = 30 \text{ MeV/c}, \quad \Delta p_z = 41 \text{ MeV/c}.
\]

and a 3-C fit was again possible. In table I the number of events for all the observed reactions is reported\(^{(x)}\).

**TABLE I**

3. - THE USE OF DEUTERON AS A NEUTRON TARGET -

3.1. Impulse approximation and spectator model.

As is always necessary, when studying a reaction on neutrons, we used deuteron as a target in our investigation of the reaction \((1)\).

The most general way to get the cross sections on free nucleon using deuterium data is provided by the Chew-Low\(^{(3)}\) method, which consists in extrapolating the differential cross section \(\sigma / (dE \pi^2 dp)\) to the neutron pole, \(a\) being the cross section on deuteron, \(E \pi^2\) the total square energy of the \(\pi^-p\) final state and \(p_S\) the momentum of the slower proton. However, since the shape of the extrapolation curve is not known, one must have a very high statistics for the lowest values of \(p_S\) in order to make a linear extrapolation meaningful. Moreover, the results obtained may be affected by the uncertainty in the determination of the unseen spectator momentum \((p_S \leq 80 \text{ MeV/c})\). Unfortunately, this is just the momentum region which is important for the extrapolation, so this method is not very powerful in a bubble chamber experiment with less than 4-constraints kinematical fit.

Assuming the impulse approximation\(^{(4)}\) (I. A.) to hold for a suitably selected sample of events, we have been able to determine the photoproduction cross-sections on free neutrons by applying the nucleon spectator model in the kinematical calculations, i.e. i) we considered the diagram of fig. 2 as dominant, ii) we assumed the cross-section on the off mass-shell nucleon to be the same as on a free nucleon, iii) we assumed the total cross-section to depend only on the final state \((\pi^-p)\) c.m. energy.

\(^{(x)}\) - On the criteria adopted for the event assignment to the various reactions see reference \((1)\).
FIG. 1 - Incident photon spectrum in the Laboratory system, as obtained by $e^+e^-$ measurements.

FIG. 2 - Diagram assumed to describe the reaction (1), accordingly to the spectator model.
The limits of validity of the I.A. in the case of deuteron have been discussed for a long time and all data on neutrons are evidently influenced by them.

Beyond these intrinsic limits, some corrections should in any case be introduced into the experimental data for:

i) the so-called Glauber effects\(^{(5)}\) i.e. shadow and multiple scattering effects.

ii) The Coulomb interaction in the final state\(^{(6)}\).

iii) The Pauli principle, which reduces the available phase space.

iv) Other final state interactions of the outgoing particles.

All these effects, which are expected to decrease with the energy, cannot be exactly calculated. An overall evaluation of these corrections may be achieved by the comparison of experimental results referring to the same reaction on free and bound protons. However, the evaluations so obtained are strongly dependent on the kinematics so that it is not easy to apply them to other reactions.

However the shadow and Coulomb effects are expected negligible (less than 1\%) in our reaction at least for \(E_{\gamma} \gg 200\) MeV.

The correction for the Pauli principle may be calculated only in a model dependent way. For example, analysing the same reaction, the ABHHM collaboration\(^{(7)}\) used the method of ref.\(^{(8)}\) which is able to take into account the Pauli principle if the spin-flip and non spin-flip amplitudes on neutrons are known. The difference found with respect to the spectator model was of the order of \(\sim 6\%) at most.

As far as the final state interaction is concerned, one can consider, for example, the \(\pi^0\) photoproduction on protons in hydrogen and deuterium\(^{(9)}\). In that case the observed differences were explained by means of a rescatterings process\(^{(10)}\).

In ref.\(^{(10)}\) the authors give an evaluation of this effect also for the charged pion photoproduction. The resulting corrections are of the same order as for the above mentioned Pauli correction, but, below 300 MeV, they go in the opposite sense.

Because of the general uncertainty, we prefer not to consider these corrections in the following.

We will now describe the criteria adopted for the selection of the events and the method used to get the cross-sections on neutrons.
In order to select the sample of events satisfying the spectator model, we made use of a Montecarlo calculation, which simulates events of reaction (1) in the following way. A photon, extracted from the experimental spectrum, induces the two step reaction
\[ \gamma + D \rightarrow p_S + Q \rightarrow p + \pi^- \]
according to the spectator model. The spectator momentum \( p_S \) is extracted according to the Gartenhaus deuteron wave function and its angular distribution is assumed to be
\[ \frac{dN_s}{d\Omega} \propto (1 + \beta_S \cos \theta_S) \]
with \( \beta_S, \theta_S \) the spectator velocity and angle in the lab. system, in order to take into account the Fermi motion in the flux factor \( \langle x \rangle \).

The decay \( Q \rightarrow p + \pi^- \) is calculated according to the phase-space distribution and, if the resulting proton momentum in the L. s. is lower than that of the spectator, the two protons are interchanged so as to reproduce the choice made for the real events. Moreover, each simulated event is weighted, according to its value of \( E_{\pi}^2 \) (total c.m. squared energy of the \( p\pi^- \) system), with the measured value of the cross-section \( \sigma_{\gamma n}(E_{\pi}^2) \).

In this way one obtains the distributions of the various quantities of interest, already corrected for all kinematical effects, to be compared with the experimental ones, in particular:

i) The spectator momentum distributions for various \( E_{\gamma} \) (L. s.) intervals;
ii) The angular distributions of the spectator in the L. s.
iii) The angular distributions of the spectator in the \( (\gamma D) \) c.m. s.

Moreover the Montecarlo calculation provides suitable correction coefficients for the experimental data due to

i) the wrong choice of the spectator proton.

---

\( \langle x \rangle \) - Notice that the cross-section formula \( \sigma \propto (n_{Ev}/n_{Inc}) \cdot (1/(v/c)) \) contains the ratio between \( v \), (the beam relative velocity with respect to the target nucleon, as measured in the L. s.) and \( c \), (the beam velocity in the L. s.). If \( \theta \) is the direction angle of the target nucleon and \( \beta \) its velocity, one has
\[ \frac{v}{c} = \sqrt{1 + \beta^2} - 2 \beta \cos \theta - 1 \approx -\beta \cos \theta \]
and, referring to the spectator nucleon, one sees that each event has to be weighted with a factor \( (1 + \beta_S \cos \theta_S) \).
ii) the loss of the events (one prong events) in which both protons have a
momentum lower than 80 MeV/c

iii) the cuts introduced in order to select the sample of events satisfying
the spectator model (see later).

Finally, if one does not weight the simulated events with the ex-
perimental cross-section, one also obtains $N \gamma(E^2) dE^2$, i.e. the pho-
ton spectrum as a function of $E^2$. This spectrum, which will be used
to determine the cross-sections, includes the effects of the kinematical
inaccessibility.$^{11}$

In Fig. 3 and 4 the experimental momentum and angular distribu-
tions of the spectator proton for different photon energy intervals (in the
L.s.) are shown. The curves are from the Montecarlo calculation. We
want to stress that the different percentages of higher momenta in the
various energy intervals are due essentially to a kinematical effect, so
that a cut on the spectator momentum does not select in the same way
at all energies. For the same reason the spectator momentum distribu-
tion is not a good index, at least at low energies, for the validity of the
spectator model.

A more selective criterion is provided by the angular distribu-
tion of the spectator in the overall ($\gamma D$) c.m.s. These distribu-
tions are shown in Fig. 5, for various $E_\gamma$ intervals.

Since this distribution is expected to be somewhat broadened
in a three-body interaction, it seems reasonable to introduce a cut in
this angle, which also has the advantage of being slightly correlated to
the spectator momentum.

Using the spectator model, we have calculated the $\cos\theta^*_S$ distri-
bution. From this prediction we can choose a $\theta^*_S$ cut that excludes 5%
of the distribution.

In fig. 6 e 7 the momentum and angular distributions of the spec-
tator proton are shown, for values of $\cos\theta^*_S$ higher and lower than the cut
value.

The effect of the cut is evident and the agreement between experi-
ment and predictions is now very satisfactory. An interesting feature of
this cut is that also events with low spectator momentum can be excluded.

In addition we also introduce the cut on the spectator momentum
($p_S < 250$ MeV/c), since above this value, the target nucleon is so far
off the mass-shell that its interpretation as a free nucleon is scarcely
meaningful.

In table II the percentages of the events which survived the above
mentioned selection criteria and the correction coefficients are given.
FIG. 3 - Momentum distributions of the spectator proton for various intervals of the photon energy (in the L.S.). The curves show the predictions of the spectator model, including the kinematical effects.
FIG. 4 - Angular distributions of the spectator proton (in the L.S.). The curves show the predictions of the spectator model, including the kinematical effects.
FIG. 5 - Angular distribution of the spectator proton in the $\gamma D$ c.m.s. The curves show the predictions of the spectator model.
FIG. 6 - Same as fig. 3, but after the θₜ cut: a) for $\cos \theta_{s}^{*} < \cos \theta_{os}^{*}$; b) for $\cos \theta_{s}^{*} > \cos \theta_{os}^{*}$ the curves, representing the predictions of the spectator model, are normalized to the events with $\cos \theta_{s}^{*} < \cos \theta_{os}^{*}$.

**FIG. 7 -** Same as fig. 4, but after the \( \theta_S^* \) cut.
3.2. - Transformation to the neutron rest system -

Since the $\gamma$ - n interaction occurs on a target in motion, one has to determine the effective photon energy from the measured quantities.

The first possibility is to do a Lorentz transformation from the L.s. to the neutron rest system, assuming that the neutron momentum before interaction is opposite to the measured spectator momentum $^{(12)}$. In this way, however, the mass of the target neutron does not correspond to that of a physical particle.

As an alternative approach $^{(1)}$, but again using the spectator model, we have parametrized our results in term of $E^2$, the squared c.m. energy of the produced ($p$ $\pi^-$) system. We assumed the effective photon energy $E'_{\gamma}$, to be that one necessary to get on a free neutron a total c.m. energy $E_{\gamma}^* \left[ E_{\gamma}^* = (E^2 - M_n^2)/(2M_n) \right]$.

In this way the comparison between the cross-sections on neutrons and protons becomes meaningful.

We want to stress that the first approach (Lorentz transformation) gives systematically higher values for the energy than the second one. (Fig. 8). This fact produces a misleading shift of the cross-section toward higher energies.

4. - TOTAL AND DIFFERENTIAL CROSS-SECTIONS -

4.1. - Total cross-section $\gamma + D \rightarrow p + p + \pi^-$. 

In Fig. 9 we show the total cross-section for the reaction $\gamma D \rightarrow pp \pi^-$ versus $E_{\gamma}$, (L.s.) in order to present the unprocessed experimental results, apart from the obvious corrections of geometrical and instrumental type (scanning efficiency, $\chi^2$ cut, geometrical losses, etc.). The latest values obtained by the ABBHHM collaboration $^{(13)}$, are reported for comparison.

4.2. - Total cross-section $\gamma + n \rightarrow p + \pi^-$. -

For the reasons stated in Sect. 3.1, we assume only those events to be acceptable, which verify the two conditions:

$$\cos \theta^x_s \leq \cos \theta^x_{os} \quad \text{and} \quad p_s \leq 250 \text{ MeV/c}.$$ 

The number of events in each $E^2$ interval is then corrected by means of the Montecarlo calculation. The corrections due to the Pauli principle, shadow and rescattering effects are not introduced for the reasons stated in Sect. 3.1.
FIG. 8 - Differences between the effective photon energies, as obtained by the Lorentz transformation $E''$, and the final state ($\pi^-p$) total energy $E'$, for various $E_\gamma$ (in the L.s.) intervals.
FIG. 9 - Total cross-sections for the reaction \( \gamma + D \rightarrow p + p + \pi^- \).
FIG. 10 - Total cross-section for the reaction $\gamma + n \rightarrow p + \pi^-$. The superimposed curves are the cross-sections for $\gamma p \rightarrow p\pi^0$ (dashed line) and $\gamma p \rightarrow n\pi^+$ (full line).
The different energy resolution for the events and for the photon spectrum measurement is also taken into account.

The resulting total cross-section as a function of $E^2$ (or $E'\gamma$) is shown in Fig. 10 and reported in Table III. The superimposed curves are the cross-sections $\gamma p \rightarrow p \pi^0$ and $\gamma p \rightarrow n \pi^+$ as obtained from ref. (14). The quoted errors are purely statistical.

We have also checked that the cross-section does not depend very much on the kinematical conditions of the spectator proton. Fig. 11 shows the ratios between the total cross-sections for different intervals of the spectator momentum. The fact that this plot is essentially flat assures us that the assumptions we have made are correct.

As already pointed out, the events with $p_s \leq 50$ MeV/c give systematically higher values for the cross-sections because the measured spectator momenta are set to zero prior to the kinematical fit and the dispersing effect of the fit itself is not accurate enough.

**FIG. 11** - Plots of the ratios $R = \sigma(p_0, 250)/\sigma(p_a, b)$ vs $E^2$, where $\sigma(p_a, b)$ is the cross-section value, obtained by the events with $a \leq p_s \leq b$.

</table>

Note: The table represents a portion of the data from Table III, showing the differential cross-section $\sigma$ (in pb) for various energy intervals $\Delta^{+}$, measured in GeV, with the angle $\theta$ (in degrees) ranging from 10 to 120 degrees.
4.3. - Total cross-section $\gamma n - p \pi^-$ without event selection.

We want now to determine the total cross-section with the assumption that all the events of the type $\gamma D \rightarrow pp\pi^-$ found can be considered as $\gamma n$ events occurring in I.A. This allows us to obtain maximal values for the cross-section on neutrons and to take into account the effect of the Fermi motion without choosing the spectator nucleon.

We want to remark that, apart from the correction factors due to the Pauli principle, this method should correspond to that used in ref. 6, and our results can be compared with those given there.

In order to obtain the cross-section, with this assumption, we proceeded in the following way. The yield of events vs. $E_\gamma$ in the L.s. is transformed into the yield vs. $E^{*2}$, taking into account the Fermi motion by means of a Montecarlo calculation. This yield combined with the photon spectrum $n_\gamma(E^{*2})dE^{*2}$, computed in the same way, gives the required cross-section. This procedure, however, causes a smearing of the cross-section, because for each $E_\gamma$ value there is a spectrum of $E^{*2}$ values, and consequently it produces a broadening of the first resonance and an apparent shift of the second resonance to higher $E^{*2}$ values.

In order to correct for this effect, we have evaluated the necessary correction coefficients, by doing the comparison, for a sample of simulated events, between the directly calculated $E^{*2}$ distribution and that obtained, with the above procedure, passing through the Lab. energy $E_\gamma$.

Fig. 12 shows the cross-section obtained, which is only slightly larger, at high $E^{*2}$ values, than that given before. If we remember that the Pauli corrections, as determined in ref. 6, are of the order of 6% at most, it becomes evident that some discrepancies between our results and those of Ref. 6 do not depend on the procedure used.

4.4. - Differential cross-sections -

For the events selected with the criteria stated in Sect. 2.1, the c.m. angular distributions for twenty $E^{*2}$ intervals were determined. They are reported in Table III. The data at small angles where the corrections (one prong event) are higher than 25% and the statistics too poor, are given without errors as indicative values.

The experimental distributions were fitted with $\cos \theta^*$ polynomials according to the formula

$$\frac{d\sigma}{d\Omega} = 2\pi(1-\beta\cos\theta^*)^{-2}\sum_{k=0}^{3} C_k \cos^K\theta^*$$
FIG. 12 - A maximal value of the total cross-section with the hypothesis that all the observed $\gamma D \rightarrow pp\pi^-$ events could be considered as $\gamma n$ events (see text).
where the factor \((1 - \beta \cos \phi^*)^{-2}\) is inserted to take explicitly into account the photoelectric term \((15)\). For the same reason the cross-section value at the pole, \(\cos \phi^* = +1/\beta\), was taken as a constraint in the fit.

In table IV and in fig. 13 the coefficients \(C_k\) are reported.

Finally we report a further check on the validity of the spectator model. In fig. 14 the ratios between the \(\pi^-\) in the backward and in the forward directions are given for different angles and momenta of the spectator proton. As one should expect, for a given \(E^{*2}\) interval, this ratio appears to be independent of the kinematical conditions of the spectator proton, thus confirming the overall consistency of the selec-
FIG. 13 - Behaviour of the coefficients of the Moravcsik polynomial fit to the angular distributions, as a function of $E^2$

...tion criteria adopted.

5. - ANALYSIS OF THE RESULTS -

In this section we discuss our data in the light of some very important theoretical questions which have recently come under examination.

5.1. - Isotensor component of the electromagnetic current.

The comparison of the total cross-sections of the pion photoproduction on protons and neutrons, in the first resonance region allows us to search for the possible existence of an isotensor term in the e.m. current.

In the past some authors emphasized the complete lack of direct experimental proofs for the assumption that in photon induced reac...

b) $\cos \theta_s < 0$
tions one should have $\Delta T \leq 1$. They suggested performing photoproduction measurements and pointed out that the comparison between the cross-sections for production of the $\Delta^+$ and $\Delta^0$ states of the $P_{33}$ (1236) resonance could throw some light on the question. In effect, if one puts

$$\sigma(\gamma n \rightarrow \Delta^0) = \sigma(\gamma p \rightarrow \Delta^+)(1+x^2),$$

from the usual isotopic decomposition (17) of the single photoproduction amplitude (including the isotensor amplitude $A_T$), $x$ is shown to be zero if $A_T = 0$.

Indeed, if one wants to determine $A_T$ without ambiguities, careful experiments should be done on the four single photoproduction reactions. At present this is premature and one has to make some assumptions on the reaction mechanism.

In particular, Sanda and Shaw (18) assumed the dominance of the $P_{33}$ resonance on the background, almost constant with energy, and calculated, for various $x$, the quantity

$$\Delta = \frac{K}{q} \left[ \sigma_T(\gamma n \rightarrow p\pi^-) - \sigma_T(\gamma p \rightarrow n\pi^+) \right]$$

by using dispersion relations and the following parametrization of the resonant multipole

$$nM_{1+}^{3/2} = pM_{1+}^{3/2}(1+x)$$

In fig. 15 the comparison between the predictions of Sanda-Shaw and the experimental data is shown. The quantity $\Delta$ has been determined by using our data and the $\pi^+$ cross-section taken from Ref. 19.

![FIG. 15 - $\Delta = q/K \left[ \sigma_T(\gamma n \rightarrow p\pi^-) - \sigma_T(\gamma p \rightarrow n\pi^+) \right]$ as a function of $E\pi^2$. The curves are the predictions (18) with $x = 0, 20$ (full line) and $x = 0$ (dashed line).]
As one can observe our results are compatible with $x = 0.2$ and an overall upward correction of about 20% to our data would be necessary to cancel this effect. Such an amount certainly cannot be attributed to the deuteron corrections discussed above, which have not been introduced in our results.

We want to remark that some energy dependence of the corrections themselves could somewhat change the experimental $\Delta$ distribution. This fact could be important, because according to Sanda and Shaw, the "dip" behaviour of the $\Delta$ distribution is more indicative than the $\Delta$ absolute values.

5.2. - T-Invariance of e.m. current. -

The comparison between the differential cross-sections for $\pi^-$ photoproduction and its inverse ($\pi^-$ radiative capture) in the first resonance region is quite sensitive to a possible T-violation in the e.m. interaction of hadrons\(^{(20)}\).

In fig. 16 we report this comparison for three values of $E^x$, using the available $\pi^- + p \rightarrow n + \gamma$ data\(^{(21)}\), suitably modified by means of the detailed balancing principle. The values for the direct reaction $\gamma n \rightarrow p\pi^-$ were calculated using the polynomial fit described in the foregoing section. The shaded band contains two standard deviations about the calculated values.

There seems to be a satisfactory agreement for energies above the first resonance region, while at $E^x = 1.245$, our results are noticeably higher than those of the inverse reaction. It is surely premature to draw definitive conclusions on this question, also considering that the inverse reaction requires further investigation because of the problem of the large ($\pi^0n$) background.

5.3. - Phenomenological fit of the differential cross-sections. -

At present the available data are not sufficient to completely describe the photoproduction processes in terms of a multipole expansion, so that in any phenomenological analysis one has to apply specific models, in order to obtain the behaviour of some multipoles.

By using our experimental angular distributions and making some reasonable assumptions, we carried out a phenomenological fit extending from 0.4 to 0.9 GeV in $E'$, by means of an isobaric model analogous to that of Walker\(^{(22)}\).

The photoproduction amplitude is assumed to be given by a linear combination of three contributions:
FIG. 16 - Comparison between the differential cross-sections for $\pi^- p \rightarrow n \gamma$ (points from ref. 21) and $\gamma n \rightarrow \pi^- p$ (shaded band).
a) Resonant amplitudes (in our energy interval we only considered $P_{33}$, $S_{11}$, $P_{11}$ and $D_{13}$).

b) Born terms with electric coupling only.

c) Non resonant background terms.

Furthermore, we have adopted the following criteria:

i) The imaginary part of each amplitude is only due to the resonant contribution which is described by a Breit-Wigner function.

ii) Consequently the non-resonant background terms are added only to the real part of the amplitude. In this way, the fit is mostly sensitive to the resonant contributions. Moreover the background terms are assumed to be constant with energy.

iii) The $P_{33}$ resonant contribution is fixed to the Walker value\(^{(22)}\). This implies that one must consider $nM_{1+}^{3/2} = pM_{1+}^{3/2}$, which seems to be non-relevant, since, above 400 MeV, only the tail of the resonance itself intervenes.

iv) In the fit two available polarization\(^{(23)}\) and asymmetry\(^{(24)}\) results are taken into account.

The fit results have been already published\(^{(1)}\) and are quoted in Table V.

We want to stress that the above fit does not claim to give the exact behaviour of the multipoles contributing to the investigated reaction, but only to extract, in the framework of the isobaric model used, the relative importance of the resonant contributions. In this sense one has also to consider the comparisons between our results and those of other fits.

The most interesting result of our fit is the very large $P_{11}$ (1470) contribution with respect to that of $D_{13}$ (1520), which is known to dominate the corresponding reaction on proton. This result is also found in the fit of Ref.(25), in which a different parametrization is assumed. Moreover, these authors, starting from the data of the present experiment, are able to derive some predictions for the reaction $\gamma n \rightarrow n \pi^0$ which agree with a recent experiment\(^{(26)}\). The $P_{11}$ contribution found is also in agreement with the predictions of ref. (27). In table VI the comparison among some recent fits\(^{(22, 25)}\) is reported.

5.4. - The $P_{11}$ (1470) resonance in photoproduction.

As already discussed in Ref. 1, the results of the phenomenological fit support the indication of $P_{11}$ formation which is given by the behaviour of the total cross-section in the second resonance region. A backward displacement of the bump, with respect to the corresponding reaction on protons is evident. Both facts suggest that $P_{11}(1470)$ strongly contributes to the photoproduction on neutrons.

Some comparison have to be made with other experiments which do not seem to show the same result. Concerning the ABHNM collaboration experiment performed with the same technique, the extracted $\gamma n$ cross-section shows a bump at higher energy which is attributed to the $D_{13}$ resonance. In our opinion the discrepancy is mainly due to the difference in the unprocessed data.

As concerns the results of ref. (23), obtained with counters by measuring the $\pi^-/\pi^+$ ratio, we want to remark that the cross-section reported by these authors is given as a function of $E_{\gamma}$ in the L.S., so that a backward shift of about 20-30 MeV could be obtained in this energy region, if the $E^*^2$ energy parametrisation was chosen. This feeling is supported by the results of a Montecarlo calculation in which we determined the $\pi^-/\pi^+$ ratio on deuteron as a function of $E_{\gamma}$ (L.S.), using our $\pi^-$ cross-section and the known $\pi^+$ cross-section. By so doing we reproduced the data of ref. (23). The comparison is shown in fig. 17.

Finally we want to point out that the $\pi^-/\pi^+$ ratio (29) passes through the unity just at 600 MeV, so that one could infer that a bump displacement between the two reactions is present.

These considerations give us sufficient confidence to make a claim for $P_{11}(1470)$ photoproduction in the reactions on neutrons.

If it is confirmed that the same does not happen on protons (22) then $P_{11}$ would belong to an SU3-antidecuplet, not provided by the simple quark model. This assignment can be confirmed by looking for the decay mode $P_{11} \rightarrow \Delta^- + \pi^0$, which would be forbidden in this case.

This analysis is in progress in double pion photoproduction on neutrons and the preliminary results (1) (in apparent disagreement with some previous indications (31)) seem to confirm the above statement.
FIG. 17 - Total cross-section of the reaction $\gamma n \rightarrow p\pi^-$. The $\pi^+$ photoproduction cross-section is also reported (dashed line).
6. - CONCLUSIONS -

From the data of an investigation of the reaction \( \gamma d \rightarrow pp\pi^- \) we were able to derive cross-sections for the reaction \( \gamma n \rightarrow p\pi^- \) by using the spectator model. The events were selected by means of a cut on the spectator angle in the \((\gamma D)\) c.m.s. and on the L.S. momentum of the spectator itself.

Numerous checks assured us of the reliability of the model and of the effectiveness of the selection cuts.

The results can be summarized as follows:

a) If the theoretical model of Sanda and Shaw is reliable, the existence of an isotensor current cannot be excluded by our experimental results, as it is by those of the ABHHM collaboration.

Our data without Pauli and final state corrections agree with the value \( x = 0.2 \) of the isotensor parameter and the above corrections, as far as we presently know, cannot cancel the effect.

Indeed, the difference between our data and those of the ABHHM collaboration appears already in the total deuteron cross-sections, that are unaffected by any deuteron effect. In our opinion, this is the main experimental fact leading us to not completely exclude an isotensor contribution.

However, we want to point out that the Sanda and Shaw test is model dependent, due to the assumptions made on the background behaviour, so our data could also not require an isotensor contribution.

Because of the importance of the problem, we are presently carrying out another deuterium run with low energy bremsstrahlung beam, in order to measure in greater detail the cross-section in the first resonance region without double photoproduction contamination.

b) If the data on the inverse reaction are reliable, the T-invariance would be violated, both with our data and, even more, with those of the ABHHM collaboration. However, \( \pi^- \) radiative capture is very difficult to be measured and the experimental data on this subject are presently not sure enough. So, we think the T-invariance still remains a completely open problem.

c) The total cross-section shows an enhancement at \( E'_{\gamma} = 580 \text{ MeV} \), which cannot be easily attributed to the expected \( D_{13}(1520) \) resonance, but rather to the \( P_{11}(1470) \) resonance, as indicated also by a phenomenological fit to the differential cross-sections.
ACKNOWLEDGEMENTS -

We wish to thank all those, who made this work possible, in particular the members of our technical staff, Messrs. P. Benvenuto, A. Della Ciana, D. Fabbri, M. Gesini, L. Maiani and of the measuring and scanning staff, C. Ciazzo, A. Cascini, C. Casella, M. Cipriano, F. Cortellessa, C. De Palo, E. D'Uscio, M. Gatta, C. Lambo, A. Montagna, A. Parmentola, C. Sogaro and C. Tornatore.
